

# Trustability of certification systems

Alexandre Kervadec

**Abstract**—This paper is a synthesis of a E.Gerck's paper : "Overview of Certification systems: X.509, CA, PGP and SKIP"[1], but not only. First, it gives an overview of (the mains) certification systems which are X.509 and CAs, PGP, SKIP, DANE and the Certificate transparency by Google, with thoughts on pros and cons of each system, on a technical point of view and about the government's stranglehold on data exchanges.

## I. OVERVIEW OF CERTIFICATION SYSTEMS

First sections talk about existing (sections I-A and I-B) or extinguished (section I-C) certification systems. Then, further sections (I-E and I-F) deals with new, not implemented yet, technologies of digital certification which may solve current issues.

### A. X.509 and CAs

X.509 and CAs[8] infrastructure is based on a directory method.

With this kind of certification system, there are three different entities, which are :

- 1) **CA : Certification Authority**, an entity that controls authentication services and management of digital certificates. It can be public (like banks with their clients), commercial (such as *Verisign* which sells its services) or private (like a compagny department, for an internal purposes).
- 2) **Subscriber** : the entity which sends informations to the CA to add it to his certificate. This entity is one that need to be trusted by the *user* entity.
- 3) **User** : ask informations about *subscribers* to CA(s), it's central to the process, since the user party is relying on the informations given by CAs and is thus at risk.

The way that certification system is the following:

- A subscriber gives informations to the CA, in order to create a digital certificate for itself in the CA directory.
- The CA receive those informations and put it in a certificate.
- A user (the public in general) receive a certificate from a subscriber. In order to authenticate this subscriber, the client ask to the CA if the transmitted certificate matches with the subscriber's identity.
- The CA answer to the user to give him the precious informations about the subscriber's identity.

There is a not outwardly perceived entity in this system, it is the Naming Authority (DN). It provides to the CA a unique distinguished name (DN) which matches to the subscriber identity in the certificate.

Note that the CA can double in NA, but they provide two

different services: the CA certificate refers to a name but does not denote it, the NA does.

The main concerns about authentication services provided by CAs are :

- The content of a certificate needs to be discussed, as well as certificate revocation. For example, a subscriber can generate multiple DN for a same CA or the same DN to multiple CAs, so maybe, a better subscriber identifier need to be added.
- Are the validation procedures for the certified data that is included in a certificate solid enough? Because each CA has its own self-defined rules (Certification Practice Statement<sup>1</sup>), which can be completely different from one CA to another.

Going deeper with user validation : DN scheme based on X.500 Recommendation, but it is not completely defined, and will (in 1998) probably not be. Also, X509 certification depends on many others such as ISO, ANSI, ITU and IETF. Thus lead to a lack of harmonization. Plus, there is a big problem with CPS (Certification Practice Statements), that also can be seen such as flexibility (for pros), because each CA answer specific needs, so no harmonization again.

Also, regarding to the law, CAs deny all leak of information from themselves.

Some kind of conclusion about harmonization (lack of), in a world wide vision, if space there is.

### B. PGP (Pretty Good Privacy)

PGP, created thanks to Phil Zimmermann researches. It has two parts: certification and encryption, following text only deals with certification.

Compared to X.509, PGP is more *internet-like*, this because of its *introducer-model* base.

PGP depends on a chain of authenticators: the users themselves. This chain forms a ring, but not in a closed way but in a mathematical way like a list or a *web-of-trust*. You may not know everyone in this ring, but you can assume that you will know somebody who know this user. You can also assume that different rings can have some contact points to guarantee the referrals.

Thus, we can figure out that PGP breaks the traditional hierarchical trust architecture with this *web-of-trust* approach.

Let's get an example<sup>2</sup>: Bob want to exchange datas with Oscar, which he didn't knew before. But Jack, a colleague of Bob's, signs Oscar's public-key certificate which he knows is

<sup>1</sup>CPS

<sup>2</sup>Example from "The PGP trust model"[4]

Figure 1. Communities of trust: Jack introduces Oscar to Bob's public-key certificate before Bob receives it.

authentic.

Oscar then forwards his signed certificate to Bob who wishes to communicate with Oscar privately.

Bob, who knows and trusts Jack as an *introducer*, find out, after verification, that Jack is among Oscar's certificate signer. Therefore, Bob can be confident that Oscar's public key is authentic.

However, had Bob not known or trusted Oscar's signers, including Jack, he would have been skeptical about the authenticity of Oscar's public-key. Oscar would have to find another introducer whom Bob trusts to sign Oscar's public-key certificate. This is illustrated in Figure 1.

This is illustrated in Figure 1, where the dotted arrow indicates "Bob trusts Jack as introducer" and the solid arrow indicates "Jack trusts Oscar's public key validity".

PGP also includes a public-key certificate and an introducer trustworthiness. They have different levels, for a public-key certificate they are:

- *Undefined*: we cannot say whether this public-key is valid or not.
- *Marginal*: this public-key *may* be valid but we cannot be sure.
- *Complete*: we can be fully confident that this public-key is valid.

For an introducer, those levels of trustworthiness are the following:

- *Full*: this public-key is fully trusted to introduce another public-key.
- *Marginal*: this public-key can be trusted to introduce another public-key, but, it is uncertain whether it is fully competent to do that.
- *Untrustworthy*: this public-key should not be trusted to introduce another, therefore any occurrence of this key as a signature on another public-key should be ignored.

Only the trustworthiness of public-key's validity is automatically evaluated by PGP. Introducer's worthiness is manually assigned by each user of to the public key, and exists only within each individual user's public-key ring<sup>3</sup>.

The big point is the use of such a tool in a world wide range: that is reasonably not possible. We can assume to use it in a

<sup>3</sup>PGP allows users to have files representing multiple *key rings* to store public or secret keys[4].

little group, where trustworthiness is effective, but in a more wide area, it is problematic to trust such a amount of people, or find trusted introducers. Furthermore, in a commercial use, there is no entity responsible when something goes wrong.

### C. SKIP (Simple Key-Management for Internet Protocol)

SKIP implements a linked-chain of two-sided node authenticators, where each node derives its informations from a sort of *directory service*.

The problem is that SKIP happens at a low level, so it is transparent to the user; also assuming that the user has no control over security or other certification choices. So it has to be complemented by a second higher level protocol. Furthermore, SKIP does not support IP translation (such as NAT behind a firewall), that makes it quite useless.

So that protocol immediately looks inappropriate for our study. In other way, SKIP does not exist anymore, so it is pointless to go further in it study.

### D. Thoughts about X.509, CAs and PGP

To be used in a commercial way (for responsibilities purpose), X.509, CAs and PGP need a centralized certification control system. However, there is a struggle between this need of centralization and the internet architecture (that is decentralized). This shows us the uselessness of centralized government controls, since we have no central government on the internet which give a world governance.

So the question emerging in there is: how can we (and do we need to) have a main control on an internet environment, to assure the goodness of datas and legitimacy of interlocutors? Some answers have been made since then (thus since the publication of the original article), answers that we are going to explain further.

### E. DANE (DNS-Based Authentication of Named Entities)

DANE is not implemented yet, but a IETF team is working on the standard.

### F. CATA: Certificate Authority Transparency and Auditability

This protocol has been developed by a Google team few years ago [6]. It is still in development [7] so it is not implemented and deployed yet. It also has to be improved, like everything in computing sciences, in the early years.

CATA's purpose is a public list of all certificates that are emitted by CAs. Thus, clients are allowed to search in that public list, and verify that the received certificate is in that list, to be validated (if it is not in the list, it shall be rejected). In that way, a (conscientious) domain administrator can have access to that list and monitor all fraudulent certificates for his domain.

For the moment, there are plenty of questions to answer like :

- Who should hold those lists?
- How many lists should be created?
- How does the revocation should work?
- What should happen if a certificate is no longer available (path unreachable)?
